1 What is a Commitment Protocol?

A commitment protocol is like a digital "sealed envelope" - it allows someone to commit to a value while keeping it secret, then later reveal both the value and proof that it matches their original commitment.

1.0.1 Two Key Properties

- Hiding: The commitment reveals nothing about the committed value
- Binding: Once committed, the committer cannot change to a different value

Two Phases:

- Commit Phase: Create and publish commitment $C = \text{Commit}(\text{message}, \text{randomness})$
- Reveal Phase: Show the message and randomness, others verify C matches

2 Specific Commitment Schemes

2.1 Pedersen Commitments

Setup: Choose group with generator g , another generator h where discrete log relationship is unknown

Commit: $C = g^m \cdot h^r$

m = message to commit to

r = random blinding factor

Reveal: Send (m, r) , verifier checks $C = g^m \cdot h^r$

2.1.1 Properties

Computationally hiding (based on discrete log assumption)

Perfectly binding (cannot find two different openings)

Homomorphic: $C_1 \cdot C_2 = g^{m_1+m_2} \cdot h^{r_1+r_2}$

2.2 Schnorr-based Commitments

2.2.1 Method 1 - Direct Commitment

Commit: $C = g^m \cdot h^r$ (same as Pedersen)

Uses Schnorr signature structure

2.2.2 Method 2 - Hash-based with Schnorr Proof

Commit: $C = \text{Hash}(m, r)$

Prove validity using Schnorr proof of knowledge

Reveal: Show (m, r) and verify hash or discrete log relation

2.3 Okamoto Commitments

Extension of Pedersen to multiple messages:

Setup: Generators $g, h_1, h_2, \dots, h_n$

Commit: $C = g^r \cdot (h_1)^{m_1} \cdot (h_2)^{m_2} \cdot (h_n)^{m_n}$

Can commit to multiple values $(m_1, m_2, \dots, m_n)$ simultaneously r is randomness

Reveal: Send all $(m_1, m_2, \dots, m_n, r)$, verify the equation

2.3.1 Properties

- Multi-message capability
- Still computationally hiding and perfectly binding
- More flexible for complex applications
